Abstract. The classical single-band uncertainty model introduced by Bertsimas and Sim \cite{BertsimasSim07} has represented a breakthrough in the development of tractable robust counterparts of Linear Programs. However, adopting a single deviation band may be too limiting in practice: in many real-world problems, observed deviations indeed present asymmetric distributions over asymmetric ranges, so that getting a higher modeling resolution by partitioning the band into multiple sub-bands is advisable. The critical aim of our work is to close the knowledge gap on the adoption of multi-band uncertainty in Robust Optimization: a general definition and intensive theoretical study of a multi-band model are actually still missing. Our new developments have been also strongly inspired and encouraged by our industrial partners, interested in getting a better modeling of arbitrary shaped distributions, built on historical data about the uncertainty affecting the considered real-world problems.

Keywords: Robust Optimization, Multi-band Uncertainty, Compact Robust Counterpart, Cutting Planes, Probabilistic Bound.

1 Introduction

A fundamental assumption in classical optimization is that all data are exact. However, many real-world problems involve data that are uncertain or not known with precision. This can be due, among other things, to erroneous measurements

\* This work was partially supported by the German Federal Ministry of Education and Research (BMBF), project ROBUKOM \cite{robkom}, grant 03MS616E, and by the DFG Research Center MATHEON - Mathematics for key technologies, project B23 “Robust optimization for network applications”.

or adoptions of approximated numerical representations. It is well-known that neglecting such uncertainty may have very bad effects: solutions that are feasible may reveal to be infeasible, as a result of small deviations from nominal data, while solutions considered optimal may turn out to be of very low quality. Such risks cannot be taken in critical applications, such as contaminant detection in water distribution networks [30] or the design of power grids [24]. Since the groundbreaking investigations by Dantzig [18], many works have thus tried to find effective ways to deal with uncertainty (see [6] for an overview).

In recent years, Robust Optimization (RO) has become a valid methodology to tackle uncertainty in optimization and has increasingly attracted the attention of practitioners, that have started many research partnerships on the topic with academic institutions (e.g., on optical network design [7], telecommunications network design [23], surgery scheduling [25]). The central feature of RO is to approach coefficient uncertainties through hard constraints, that restrict the feasible set maintaining only robust solutions, i.e. solutions protected against deviations. For an exhaustive introduction to theory and applications of RO, we refer the reader to the book by Ben-Tal et al. [4] and to the recent survey by Bertsimas et al. [6].

One of the most successful and widely-adopted RO approach is the so-called Γ-scenario set (BS), introduced by Bertsimas and Sim in [8]. The uncertainty model of BS assumes that each uncertain coefficient $a$ is a symmetric and bounded random variable, taking value in the symmetric interval $[\bar{a} - d, \bar{a} + d]$, where $\bar{a}$ is the nominal value of $a$ and $d$ is the maximum deviation from $\bar{a}$. Furthermore, the uncertainty set adopts a parameter $\Gamma > 0$ to represent the maximum number of coefficients that are allowed to deviate from their nominal value. These modeling assumptions lead to a compact RO model that preserves the features of the original nominal model. However, the use of a single deviation band may greatly limit the power of modeling uncertainty, as noted, for example, even by Sim and colleagues in [16]. This is particularly evident in real-world problems, where it is common to have asymmetric probability distributions of the deviations, that are additionally defined over non-symmetric intervals. In such cases, neglecting the inner-band behavior and just considering the extreme values like in BS may lead to a rough estimate of the deviations and thus to unrealistic uncertainty set, which either overestimate or underestimate the overall deviation. Having a higher modeling resolution would therefore be very desirable. This can be accomplished by breaking the single band into multiple and narrower bands, each with its own $\Gamma$ value.

We remark that investigating the adoption of a multi-band uncertainty set and studying the theoretical properties of the resulting model have been discussed with and strongly encouraged by our industrial partners, such as British
Outline of our contributions. In this work, we study the robust counterpart of a Mixed-Integer Linear Program (MILP) with uncertain coefficient matrix, when a multi-band uncertainty set is considered. As previously noted, our main aim is to fill the knowledge gap on multi-band uncertainty in RO by presenting new theoretical results on this topic. Specifically, we:

1. introduce a general definition of multi-band uncertainty (Section 1.1);
2. characterize a family of dominating uncertainty scenarios (Section 1.1);
3. derive a compact formulation for the robust counterpart of a MILP, whose size is smaller than that presented by us in [12,13] (due to the new dominance results) (Section 2);
4. define an efficient method for the separation of robustness cuts (i.e., cuts that impose robustness), based on solving a min-cost flow instance. In particular, we propose an alternative proof to the one that we presented in [12]; the new proof takes advantage of the new dominance results and highlights the correspondence between the dominating uncertainty scenarios and the integral flows of an auxiliary min-cost flow instance (Section 3);
5. study the properties of a special subfamily of uncertain MILPs, namely pure Binary Programs with uncertainty just affecting the objective function, and we show that if the nominal problem is polynomially solvable, then also its counterpart remains polynomially solvable (Section 4);
6. derive a data-driven bound on the probability that an optimal robust solution is infeasible, due to deviations that are not considered by the uncertainty set. We define the bound data-driven, as it exploits samples of the unknown arbitrary distribution of an uncertain coefficient (Section 5).

We strongly remark that our original results are not obtained by simply extending the proofs of [8] for single-band uncertainty, but need alternative proof strategies. For example, the separation of cuts imposing robustness does not
anymore reduce to a trivial ordering problem (see [21]), but, as we have proved, corresponds to solve a min-cost flow problem (see Section 3 for details).

Moreover, our bound on the probability of robust infeasibility differs from those proposed in the two cornerstone RO papers [5] and [8]: in contrast to the bounds of these two works, that use a priori distributional information (symmetric distribution over symmetric single range), we derive a data-driven bound by exploiting samples of the unknown distribution. This type of bound is particularly suitable in real-world problems, where historical data about the deviations are commonly available. Moreover, we think that a data-driven bound is also more in accordance with the spirit of multi-band uncertainty: multi-band is indeed particularly suitable to build strongly data-driven uncertainty sets, that can effectively approximate the shape of histograms built on historical data [9].

Finally, we note that we first presented the results about the compact robust counterpart and the efficient separation of robustness cuts in [12], where we focused attention on Linear Programs. A revised version of the work with the alternative proof for the separation of robustness cut is presented in [13]. Additionally, we remark that in this paper we have decided to focus just on the theoretical results. However, we have already got promising computational results on realistic instances of real-world problems (specifically, network design problems), where the uncertainty set has been defined in collaboration with our industrial partners. We refer the reader to [12] and [15] for a description of these results.

**Review of related literature and comparisons with our work.** While writing this paper, we became aware that a model similar to ours was presented in a very recent technical report ([26]). However, we remark that: 1) in our former papers [12], [13] and [14], we already introduced the multi-band model along with theoretical results similar to those presented in [26]; 2) the uncertainty model of [26] is a (very) special case of our multi-band model, so our results are (much) more general. Moreover, in contrast to our model, the model of [26] cannot shape any arbitrary distribution, because of its limiting assumptions (symmetric deviation range, symmetric distribution of deviations, probability of deviation that decreases as the value of the deviation increases). Such hypotheses, in particular those on symmetry, greatly reduce the ability of modeling real uncertainty distributions and can result in excessive conservatism, as clearly pointed out even by Sim and colleagues in [16].

Reducing the conservatism of robust solutions associated with first classic works like [5] and [8] has been an important question approached in several works. We recall here some more significant references, referring the reader to [10] for a broader view. In [16], the conservatism is mitigated by defining new deviations measures, aimed at capturing asymmetrical distributions. In [2], a “soft robust” model is introduced by using the concept of risk measure, reducing the conservatism at the price of lower probabilistic guarantees of robustness. The concept of risk measure is also used in [3] to develop rules for constructing good uncertainty sets that reduce conservatism. Finally, another interesting approach based on the BS uncertainty model is constituted by “light robustness” [20].
this approach adopts a hard upper bound on the objective value to control conservatism and aims at finding the most robust solution that satisfies the bound.

All these works successfully reach the objective of guaranteeing a reduction in conservatism, proposing new interesting approaches. However, at the same time, we think that they miss the elegant simplicity and easiness of access that characterize BS and that have been undoubtedly decisive for its success also among practitioners and scholars from outside the Operations Research community. Concerning this point, we note that our work differs from the previously cited ones: we defined and studied a general multi-band uncertainty model that overcomes remarkable limitations of BS, while trying to maintain the simplicity of BS and offering straightforward ways to build uncertainty sets strongly based on available historical data. We remark that the simplicity of access and the data-driven characteristics have been highly requested by our industrial partners (e.g., Nokia Siemens Networks) in several industrial collaborations. Our modeling and theoretical developments are thus also inspired by and satisfy practical industrial needs [23].

1.1 Model and Notation.

In this work, we study the robust counterpart of Mixed-Integer Linear Programming Problems whose coefficient matrix is subject to uncertainty and the uncertainty set is modeled through multiple deviation bands. We start by considering a generic deterministic problem of the form:

\[
\begin{align*}
\text{max} & \quad \sum_{j \in J} c_j x_j \\
\text{subject to} & \quad \sum_{j \in J} a_{ij} x_j \leq b_i \quad i \in I \\
& \quad x_j \geq 0 \quad j \in J \\
& \quad x_j \in \mathbb{Z}_+ \quad j \in J \subseteq J
\end{align*}
\]

where \( I = \{1, \ldots, m\} \) and \( J = \{1, \ldots, n\} \) denote the set of constraint and variable indices, respectively. Assuming that the uncertainty affects only the coefficient matrix does not limit the generality of our study: indeed, 1) if the r.h.s. vector \( b \) is uncertain, we introduce an additional variable \( x_{n+1} : x_{n+1} = 1 \) and include \( b \) as a column of the matrix \( A \); 2) if the cost vector \( c \) is uncertain, we introduce an additional variable \( L \), add the constraint \( c'x \geq L \) and change the objective function into \( \text{max} L \).

We assume that the value of each coefficient \( a_{ij} \) is uncertain and is equal to the summation of a nominal value \( \overline{a}_{ij} \) and a deviation lying in the range \([d_{ij}^-K, d_{ij}^+K]\), where \( a_{ij}^K, d_{ij}^K \in \mathbb{R} \) represent the maximum negative and positive deviations from \( \overline{a}_{ij} \), respectively. The actual value \( a_{ij} \) thus lies in the interval \([\overline{a}_{ij} + d_{ij}^-K, \overline{a}_{ij} + d_{ij}^+K]\).
We derive a generalization of the Bertsimas-Sim uncertainty model by partitioning the single deviation band \([d_{ij}^{K^-}, d_{ij}^{K^+}]\) of each coefficient \(a_{ij}\) into \(K\) bands, defined on the basis of \(K\) deviation values:

\[-\infty < d_{ij}^{K^-} < \cdots < d_{ij}^{-2} < d_{ij}^{-1} < d_{ij}^0 = 0 < d_{ij}^1 < d_{ij}^2 < \cdots < d_{ij}^{K^+} < +\infty.\]

Through these values, we define: 1) a set of positive deviation bands, such that each band \(k \in \{1, \ldots, K^+\}\) corresponds to the range \((d_{ij}^{k-1}, d_{ij}^k]\); 2) a set of negative deviation bands, such that each band \(k \in \{K^- + 1, \ldots, -1, 0\}\) corresponds to the range \((d_{ij}^{k-1}, d_{ij}^k]\) and band \(k = K^-\) corresponds to the single value \(d_{ij}^{K^-}\) (the interval of each band but \(k = K^-\) is thus open on the left). With a slight abuse of notation, in what follows we indicate a generic deviation band through the index \(k\), with \(k \in K = \{-1, 0, 1, \ldots, K^+\}\) and the corresponding range by \((d_{ij}^{k-1}, d_{ij}^k]\).

Additionally, for each band \(k \in K\), we define a lower bound \(l_k\) and an upper bound \(u_k\) on the number of deviations that may fall in \(k\), with \(l_k, u_k \in \mathbb{Z}\) satisfying \(0 \leq l_k \leq u_k \leq n\). In the case of band \(k = 0\), we assume that \(u_0 = n\), i.e. we do not limit the number of coefficients that take their nominal value. Furthermore, we assume that \(\sum_{k \in K} l_k \leq n\), so that there always exists a feasible realization of the coefficient matrix.

We remark that, in order to avoid an overload of the notation, we assume that \(\sum_{ij} a_{ij} = \pi_{ij} + d_{ij}^S\). We say that a scenario \(S\) is feasible and belongs to the set \(\mathcal{S}_M\) if and only if the deviations \(d_{ij}^S\) satisfy the following three properties:

\[
\begin{align*}
  l_k &\leq |\{j \in J : d_{ij}^S \in (d_{ij}^{k-1}, d_{ij}^k]\}| \leq u_k & i \in I, k \in K \setminus \{K^-, K^+\}, \\
  l_K^- &\leq |\{j \in J : d_{ij}^S = d_{ij}^{K^-}\}| \leq u_K^- & i \in I.
\end{align*}
\]

Properties (1) enforces that the deviation of each coefficient lies in the corresponding overall deviation range. Properties (2-3) guarantee that, for each constraint and deviation band, the number of deviations falling in the band must respect the corresponding bounds.

Before deriving a compact formulation for the robust counterpart of (MILP), we introduce some structural properties of the multi-band scenario set \(\mathcal{S}_M\). To this end, we first define the band partition of a scenario \(S \in \mathcal{S}_M\) as the family of subsets:

\[
J_{ik}(S) = \{j \in J : d_{ij}^S \in (d_{ij}^{k-1}, d_{ij}^k]\}, \quad i \in I, k \in K.
\]

Each subset \(J_{ik}(S)\) includes the indices \(j \in J\) of constraint \(i \in I\) whose deviation falls in band \(k\). It is easy to verify that such subsets define a partition of \(J\) for
The robust counterpart of the problem (MILP) under a multi-band scenario set

2 A Compact Robust MILP Counterpart

under multi-band uncertainty.

We call a scenario \( S \) dominates \( S' \) if \( \exists d \in \mathbb{R} \) such that \( S \) dominates \( S' \) by \( d \). The robust counterpart of (MILP) by limiting our attention to those scenarios that satisfy the following properties: 1) each deviation attains the maximum value of the band in which it falls; 2) the cardinality of each subset of the band partition equals the value associated with the profile of the considered feasible scenario.

Lemma 1. Let \( S \in S_M \) be a feasible scenario.

1. If \( d_{ij}^S \neq d_{ij}^k \) for any \( j \in J_k(S), i \in I, k \in K \), then there exists a feasible scenario \( S' \in S_M \) dominating \( S \).
2. If \( |J_k(S)| \neq \theta_k \) for any \( i \in I, k \in K \), then there exists a feasible scenario \( S' \in S_M \) dominating \( S \).

Proof. 1) Since \( x \geq 0 \) and the values falling in a band are bounded from above by \( d_{ij}^k \), a scenario \( S' \) such that \( d_{ij}^{S'} = d_{ij}^k \) for each \( j \in J_k(S), i \in I, k \in K \) dominates the scenario \( S \).

2) Let \( k^1 \) be the highest band \( k \in K \) such that \( |J_k(S)| \neq \theta_k \). Then there exists a band \( k^2 < k^1 \) such that \( |J_{k^2}(S)| > \theta_{k^2} \). Let \( \mu \in J_{k^2} \). We define the feasible scenario \( S' \) by setting \( d_{ij}^S = d_{ij}^{k^2} \) and \( d_{ij}^S = d_{ij}^S \) for \( j \neq \mu \). Then \( S' \) dominates \( S \).

We call a scenario \( S \in S_M \) that satisfies the properties of Lemma 1 profile and bound valid. Due to Lemma 1 in the rest of the paper we can limit our attention to these scenarios. We now proceed to study the robust counterpart of (MILP) under multi-band uncertainty.

2 A Compact Robust MILP Counterpart

The robust counterpart of the problem (MILP) under a multi-band scenario set \( S_M \) can be equivalently written as:

\[
\max \sum_{j \in J} c_j x_j
\]
where $\text{DEV}_i(x, S_M)$ is the maximum total deviation induced by the scenario set $S_M$ for a feasible solution $x$ when constraint $i$ is considered. Due to Lemma 1, $\text{DEV}_i(x, S_M)$ is equal to the optimal value of the following pure 0-1 Linear Program (note that in this case index $i$ is fixed):

$$\text{DEV}_i(x, S_M) = \max \sum_{j \in J} \sum_{k \in K} d_{ij}^k x_j y_{ij}^k$$ (DEV01)

$$\sum_{j \in J} y_{ij}^k = \theta_k$$

$$k \in K$$ (7)

$$\sum_{k \in K} y_{ij}^k \leq 1$$

$$j \in J$$ (8)

$$y_{ij}^k \in \{0, 1\}$$

$$j \in J, k \in K.$$ (9)

The generic binary variable (9) is equal to 1 if coefficient $a_{ij}$ deviates in band $k$ and is 0 otherwise. The constraints (7) impose the profile of $S_M$ on the number of coefficients deviating in each band $k$. The constraints (8) ensure that each coefficient deviates in at most one band (actually these should be equality constraints, but, for the assumption $u_0 = n$ made in Section 1.1, we can consider inequalities). An optimal solution of (DEV01) thus defines a distribution of the coefficients among the bands which maximizes the total deviation w.r.t. the nominal values, while respecting the bounds on the number of deviations of each band.

We now prove that the robust counterpart of (MILP) under a multi-band scenario set $S_M$ can be reformulated as a compact Mixed-Integer Linear Program. To this end, we first consider first the linear relaxation (DEV01-RELAX) of (DEV01) and show that it presents the following nice property.

**Proposition 1.** The polytope described by the constraints of (DEV01-RELAX) is integral.

**Proof.** We prove the integrality by showing that the coefficient matrix is totally unimodular. Consider first the linear relaxation of (DEV01):

$$\max \sum_{j \in J} \sum_{k \in K} d_{ij}^k x_j y_{ij}^k$$ (DEV01-RELAX)

$$\sum_{j \in J} y_{ij}^k = \theta_k$$

$$k \in K$$ (10)

$$\sum_{k \in K} y_{ij}^k \leq 1$$

$$j \in J$$ (11)

$$y_{ij}^k \geq 0$$

$$j \in J, k \in K.$$ (12)
where we dropped constraints $y_{ij}^k \leq 1$, that are dominated by constraints \(8\).

The constraints of (DEV01-RELAX) have the following matrix form:

$$
F_i y_i = \begin{pmatrix}
I & I & \cdots & I \\
\cdots & \cdots & \cdots & \cdots \\
1 & 1 & \cdots & 1 \\
\end{pmatrix}
\begin{pmatrix}
y_{i1}^K^- \\
y_{i1}^K^+ \\
y_{ij} \\
y_{im}^K^- \\
y_{im}^K^+ \\
\end{pmatrix}
\leq \begin{pmatrix}
\theta_k \\
\cdots \\
1 \\
\end{pmatrix}
= g_i
$$

It is easy to verify that $F_i$ is the incidence matrix of a bipartite graph: the elements of the two disjoint set of nodes of the graph are in correspondence with the rows of the two distinct layers of block in $F_i$. Moreover, every column has exactly two elements that are not equal to zero: one in the upper layer of blocks and one in the lower layer. Being the incidence matrix of a bipartite graph, $F_i$ is a totally unimodular matrix \([27]\). Since $F_i$ is totally unimodular and the vector $g_i$ is integral, it is well-known that the polytope defined by $F_i \leq g_i$ and $y_i \geq 0$ is integral, thus completing the proof.

Due to this integrality property, we can use strong duality to prove the main result of this section.

**Theorem 1.** The robust counterpart of a Mixed-Integer Linear Program under the multi-band scenario set $S_M$ is equivalent to the following compact Mixed-Integer Linear Program:

$$
\max \sum_{j \in J} c_j x_j \quad (\text{Rob-MILP})
$$

$$
\sum_{j \in J} a_{ij} x_j + \sum_{k \in K} \theta_k w_i^k + \sum_{j \in J} z_{ij} \leq b_i \quad i \in I
$$

$$
w_i^k + z_{ij} \geq \bar{d}_{ij} x_j \quad i \in I, j \in J, k \in K
$$

$$
z_{ij} \geq 0 \quad i \in I, j \in J
$$

$$
w_i^k \in \mathbb{R} \quad i \in I, j \in J
$$

$$
x_j \geq 0 \quad j \in J
$$

$$
x_j \in \mathbb{Z}_+ \quad j \in J_Z \subseteq \mathbb{Z}.
$$

**Proof.** As first step, consider the dual problem of (DEV01-RELAX):

$$
\min \sum_{k \in K} \theta_k w_i^k + \sum_{j \in J} z_{ij} \quad (\text{DEV01-RELAX-DUAL})
$$
\[
\begin{align*}
  w_k^i + z_{ij} & \geq d_{ijk}^i x_j & j \in J, k \in K \\
  z_{ij} & \geq 0 & j \in J \\
  w_k^i & \in \mathbb{R} & k \in K,
\end{align*}
\]

where the dual variables \( w_k^i, z_{ij} \) are respectively associated with the primal constraints (10, 11) of (DEV01-RELAX) defined for constraint \( i \).

Since (DEV01-RELAX) is feasible and bounded by definition of the scenario set \( S_M \), also (DEV01-RELAX-DUAL) is feasible and bounded and the optimal values of the two problems are the same (strong duality). Then, by Proposition 1, we can replace the maximum total deviation \( \text{DEV}_i(x, S_M) \) with problem (DEV01-RELAX-DUAL), obtaining the compact Mixed-integer Linear Program (Rob-MILP). This concludes the proof.

\[\square\]

In comparison to (MILP), this compact formulation uses \( K \cdot m + n \cdot m \) additional variables and includes \( K \cdot n \cdot m \) additional constraints. Due to the dominance results, we remark that the new formulation (Rob-MILP) has \( K \cdot m \) variables less than the compact counterpart that we presented in [12]. Moreover, we note that when (MILP) does not include integer variables (i.e., \( J_Z = \emptyset \)) and is thus a pure Linear Program, (Rob-MILP) is a pure Linear Program as well.

3 Separation of Robustness Cuts

As an alternative to directly solving the compact robust counterpart (Rob-MILP), we have investigated the development of a cutting-plane algorithm: we start by solving the nominal problem (MILP) and then test if the optimal solution is robust. If not, we generate a cut that imposes robustness (robustness cut) and we add it to the problem. This initial step can then be iterated as in a typical cutting plane method [27].

Testing whether a solution \( x \in \mathbb{R}^{n-|J_Z|} \times \mathbb{Z}^{|J_Z|} \) is robust, corresponds to confirming that \( \sum_{j \in J} a_{ij} x_j + \text{DEV}_i(x, S_M) \leq b_i \) for every constraint \( i \in I \). In the case of the Bertsimas-Sim model, this is very simple and merely requires to sort the deviations and choose the largest \( \Gamma_i \) values [21]. In the case of a multi-band scenario set, this simple approach does not guarantee the robustness of a computed solution. However, in the following theorem we prove that testing the robustness of a solution corresponds to solving a min-cost flow problem [1]. We recall that an integral min-cost flow of value \( n \) can be computed in polynomial time [1].

**Theorem 2.** Let \( x \in \mathbb{R}^{n-|J_Z|} \times \mathbb{Z}^{|J_Z|} \) and let \( S_M \) be a multi-band scenario set. Moreover, let \((G,c)_x^i\) be the min-cost flow instance corresponding to \( x \) and a constraint \( i \in I \) of (MILP) and built according to the rules specified in the proof. The solution \( x \) is robust for constraint \( i \) w.r.t. \( S_M \) if and only if

\[
\bar{a}_i'x - c_i^*(x) \leq b_i
\]

where \( c_i^*(x) \) is the value of a min cost flow in the instance \((G,c)_x^i\).
Proof. We prove the statement by showing that there exists a one-to-one correspondence between the scenarios $S \in S_M$ satisfying the profile and bound properties (see Lemma 11) and the integral flows $f \in F_i$ associated with the min-cost flow instance $(G, c)^f_k$ (defined below), with cost relation
\[
c(f) = - \sum_{j \in J} d^S_{ij} x_j.
\]

Thus,
\[
DEV_i(x, S_M) = \max_{S \in S_M} \sum_{j \in J} d^S_{ij} x_j = - \min_{f \in F_i} c(f) = -c^*_i(x),
\]

which concludes the proof.

The min-cost flow instance $(G, c)^f_k$, is defined as follows. The directed graph $G$ contains one vertex $v_j$ for each variable index $j \in J$, one vertex $w_k$ for each band $k \in K$ and two vertices $s,t$ that are the source and the sink of the flow, i.e. $V = \bigcup_{j \in J} \{v_j\} \cup \bigcup_{k \in K} \{w_k\} \cup \{s,t\}$. The set of arcs $A$ is the union of three sets $A_1,A_2,A_3$. The set $A_1$ contains one arc from $s$ to every vertex $v_j$, i.e. $A_1 = \{(s,v_j) : j \in J\}$. The set $A_2$ contains one arc from every vertex $v_j$ to every vertex $w_k$, i.e. $A_2 = \{(v_j,w_k) : j \in J, k \in K\}$. Finally, the set $A_3$ contains one arc from every vertex $w_k$ to the sink $t$, i.e. $A_3 = \{(w_k,t) : k \in K\}$. By construction, $G(V,A)$ is bipartite and acyclic. To each arc $a \in A$, we associate an upper bound $u_a$ on the flow that can be sent on $a$ and a cost $c_a$ of sending one unit of flow on $a$. These two values are set in the following way: $(1,0)$ when $a = (s,v_j) \in A_1$; $(1,-d^S_{ij}x_j)$ when $a = (v_j,w_k) \in A_2$; $(\theta_k,0)$ when $a = (w_k,t) \in A_3$. Finally, the amount of flow that must be sent through the network from $s$ to $t$ is equal to $n$.

We denote by $F_i$ the set of feasible integral flows of value $n$ of the min-cost flow instance $(G, c)^f_k$. The cost of an $(s,t)$-flow $f \in F_i$ is defined by $c(f) = \sum_{a \in A} c_a f_a$.

Given a scenario $S \in S_M$ that satisfies the profile and bound properties, we construct an integral flow $f$ for the min-cost flow instance $(G, c)^f_k$, in the following way:
\[
\begin{align*}
 f_{(s,v_j)} &= 1 & \forall j \in J \\
 f_{(v_j,w_k)} &= 1 \iff d^S_{ij} = d^k_{ij} & \forall j \in J, k \in K \\
 f_{(w_k,t)} &= \theta_k & \forall k \in K.
\end{align*}
\]

The flow $f$ respects the arc capacities and has a value of $n$. Since each deviation is assigned by $S$ to exactly one band, $f$ also satisfies flow conservation in each vertex $v_j$. Furthermore, $S$ assigns exactly $\theta_k$ values to band $k$, and thus
\[
\sum_{j \in J} f_{(v_j,w_k)} = |J_k(S)| = \theta_k = f_{(w_k,t)}.
\]

Hence, $f$ is in $F_i$ and by definition of the arc costs $-c(f) = \sum_{j \in J} d^S_{ij} x_j$.

Given a feasible integral flow $f \in F_i$ of value $n$ and cost $c(f)$ of the min-cost flow instance $(G, c)^f_k$, we construct a scenario $S \in S_M$ satisfying the profile and bound properties in the following way:
\[
d^S_{ij} = d^k_{ij} \iff f_{(v_j,w_k)} = 1 & \forall j \in J, k \in K.
\]
This definition is valid, since each arc \((s, v_j)\) carries one unit of flow and thus due to flow conservation exactly one arc \((v_j, w_k)\) carries flow. Furthermore, since \(\sum_{k \in K} \theta_k = n\), exactly \(\theta_k\) arcs with positive flow value enter \(w_k\) and therefore \(|J_{ik}(S)| = \theta_k\). Summing up,

\[
e(f) = \sum_{j \in J} \sum_{k \in K} -d_{ij}^k x_j f_{(v_j, w_k)} = \sum_{k \in K} \sum_{j \in J, (S)} -d_{ij}^k x_j = \sum_{j \in J} -d_{ij}^k x_j.
\]

This concludes the proof. \(\square\)

From Theorem 2 we can immediately derive the following corollary:

**Corollary 1.** A solution \(x \in \mathbb{R}^{n−|J|} \times \mathbb{Z}^{|J|}_+\) is robust w.r.t. \(S_M\) if and only if

\[
\bar{\alpha}^j x - c_j^* (x) \leq b_i \quad \forall i \in I,
\]

where \(c_j^* (x)\) is the value of a minimum cost flow in \((G, c)_x^j\).

According to this corollary, we can test the robustness of a solution \(x \in \mathbb{R}^{n−|J|} \times \mathbb{Z}^{|J|}_+\) by computing an integral flow \(f^j\) of minimum cost \(c_j^* (x)\) in \((G, c)_x^j\) for every \(i \in I\). If \(\bar{\alpha}^j x - c_j^* (x) \leq b_i\) for every \(i \in I\), then \(x\) is robust feasible. Otherwise \(x\) is not robust and there exists an index \(i \in I\) such that \(\bar{\alpha}^j x - c_j^* (x) > b_i\) and thus

\[
\sum_{j \in J} \bar{a}_{ij} x_j + \sum_{j \in J} \sum_{k \in K} -d_{ij}^k x_j f_{(v_j, w_k)} \leq b_i \quad \text{(16)}
\]

is valid for the polytope of the robust solutions and cuts off the solution \(x\).

### 4 0-1 Minimization Problems with Cost Uncertainties

In this section, we present results on a subfamily of Mixed-Integer Linear Programs, namely pure Binary Programs (BP), and consider the case in which uncertainty only affects the objective function. Specifically, we investigate Binary Programs of the form:

\[
\min \ c^j x \quad \text{(BP)}
\]

with non-negative cost vector, i.e. \(c_j \geq 0\), for all \(j \in J = \{1, \ldots, n\}\). Relevant problems like the minimum spanning tree problem, the maximum weighted matching problem and the shortest path problem belong to this class of problems.

We study the robust version (Rob-BP) of the previous problem under multi-band uncertainty affecting just the cost vector. More formally, for each element \(j \in J\) we are given the nominal cost \(\bar{c}_j\) and a sequence of \(K^+ + 1\) deviation values \(d_{ij}^k\), with \(k \in K = \{0, \ldots, K^+\}\), such that \(0 = d_{ij}^0 < d_{ij}^1 < \ldots < d_{ij}^{K^+} < \infty\) (note that in contrast to Section 2 we consider only positive deviations). Through
these values, we define: 1) the zero-deviation band corresponding to the single value \( d_0^j = 0 \); 2) a set \( K^+ \) of positive deviation bands, such that each band \( k \in K^+ \) corresponds to the range \((d_j^{k-1}, d_j^k)\). Furthermore, integer values \( l_k, u_k \in \mathbb{Z}, 0 \leq l_k \leq u_k \leq n \) represent the lower and upper bounds on the number of deviations falling in each band \( k \in K \).

Since (BP) is a special case of (MILP), to define its robust counterpart (Rob-BP) we can apply Lemma 1 and Theorem 1. The resulting problem could be solved by means of a commercial MIP solver. However, in the following lemma, we prove that there exists an optimal solution of (Rob-BP) with a peculiar structure, that we take advantage of to develop an efficient algorithm for the deterministic problem.

**Lemma 2.** There exists an optimal solution \((x^*, w^*, z^*)\) of (Rob-BP) such that \( w^*_k \in \{0, d_1^k, \ldots, d_n^k\} \), for all \( k \in K \).

**Proof.** Since (BP) is a special case of (MILP), we can apply Lemma 1 and Theorem 1 to define the robust counterpart of (BP) and to obtain the following compact formulation:

\[
\begin{align*}
\min & \quad \sum_{j \in J} c_j x_j + \sum_{k \in K} \theta_k w_k + \sum_{j \in J} z_j \\
\text{subject to} & \quad w_k + z_j \geq d_j^k x_j, \quad j \in J, k \in K \quad (17) \\
& \quad w_k \geq 0, \quad k \in K \\
& \quad z_j \geq 0, \quad j \in J \\
& \quad x \in X,
\end{align*}
\]

where we recall that the integers \( \theta_k \) denote the profile of \( S_M \) (see Section 1).

Let \((x^*, w^*, z^*)\) be an optimal solution of (Rob-BP) and \( Z^* = \sum_{j \in J} c_j x_j^* + \sum_{k \in K} \theta_k w_k^* + \sum_{j \in J} z_j^* \) be the corresponding optimal value. Then \((w^*, z^*)\) is the optimal solution of the problem:

\[
\begin{align*}
Z^* = \sum_{j \in J} c_j x_j^* + \min_{k \in K} & \quad \sum_{k \in K} \theta_k w_k + \sum_{j \in J} z_j \\
\text{subject to} & \quad w_k + z_j \geq d_j^k x_j^*, \quad j \in J, k \in K \quad (18) \\
& \quad w_k \geq 0, \quad k \in K \\
& \quad z_j \geq 0, \quad j \in J.
\end{align*}
\]

Consider now the dual of problem (18):

\[
\max \sum_{k \in K} \sum_{j \in J} d_j^k x_j^* \cdot t_k \quad (19)
\]

\[
\begin{align*}
\sum_{j \in J} t_k & \leq \theta_k, \quad k \in K \\
\sum_{k \in K} t_k & \leq 1 \quad (j \in J) \\
t_k \geq 0, & \quad j \in J, k \in K.
\end{align*}
\]
The corresponding coefficient matrix is totally unimodular (see the proof of Proposition 1), so there exists a binary optimal solution to problem (19). Furthermore, since by definition \( \sum_{k \in K} \theta_k = n \) and \( d_k^j x_j^* \geq 0 \), for all \( k \in K, j \in J \), there also exists a binary optimal solution \( t_{kj}^* \in \{0, 1\} \), for all \( k \in K, j \in J \) such that:

\[
\sum_{j \in J} t_{kj}^* = \theta_k \quad \forall k \in K \tag{20}
\]
\[
\sum_{k \in K} t_{kj}^* = 1 \quad \forall j \in J . \tag{21}
\]

Let \( t_{kj}^* \) be a binary optimal solution to (19) that satisfies (20 - 21) and let \((\bar{w}, \bar{z})\) be a feasible solution to the primal problem (18). By the well-known complementary slackness conditions, \((\bar{w}, \bar{z})\) is optimal to (18) if and only if:

\[
t_{kj}^* (\bar{w}_k + \bar{z}_j - d_k^j x_j^*) = 0 \quad \forall j \in J, k \in K \tag{22}
\]
\[
\bar{w}_k \left( \theta_k - \sum_{j \in J} t_{kj}^* \right) = 0 \quad \forall k \in K \tag{23}
\]
\[
\bar{z}_j \left( 1 - \sum_{k \in K} t_{kj}^* \right) = 0 \quad \forall j \in J . \tag{24}
\]

We can directly focus attention on the first set of conditions, as conditions (23-24) are satisfied by the choice of \( t_{kj}^* \). To conclude the proof, we first introduce sets \( J_k = \{ j \in J : t_{kj}^* = 1 \}, k \in K \). Due to (21), this defines a partition of \( J \), i.e. \( J = \bigcup_{k \in K} J_k \) and \( J_k \cap J_{k'} = \emptyset \), for all \( k, k' \in K, k \neq k' \). A feasible solution \((\bar{w}, \bar{z})\) is optimal for the primal problem (18) if and only if:

\[
\bar{w}_k + \bar{z}_j = d_k^j x_j^* \quad \forall k \in K, j \in J_k .
\]

Such a solution can be built by setting \( \bar{w}_k = \min_{j \in J_k} \{ d_k^j x_j^* \} \) if \( |J_k| \geq 1 \) and \( \bar{w}_k = 0 \) otherwise, and by setting \( \bar{z}_j = d_k^j x_j^* - \bar{w}_k \).

This defines a solution \((\bar{w}, \bar{z})\) that is optimal to (18) and such that \( \bar{w}_k \in \{0, d_k^1, \ldots, d_k^n\} \), for all \( k \in K \), since \( x_j^* \) is binary. Moreover, \((\bar{w}, \bar{z})\) together with \( x_j^* \) constitutes a robust optimal solution to (Rob-BP), thus concluding the proof. \( \square \)

This observation leads to the following algorithm, which solves the robust problem under multi-band uncertainty to optimality.
where the second equality follows from the binary nature of $x$. Return:
and then:

$\min_{x \in X} c(x)$

Step 3: choose $z^*$ from $D$ with minimum cost $\min_{x \in X} c(x)$.

Return: $x^*(w^*)$ as optimal robust solution.

---

**Theorem 3.** Algorithm 1.1 computes an optimal robust solution for problem (BP). If there is an algorithm to solve the deterministic optimization problem $\min_{x \in X} c(x)$ in polynomial time, Algorithm 1.1 has a polynomial run-time for a constant number of deviation bands.

**Proof.** Let $(x^*, w^*, z^*)$ be an optimal solution of (Rob-BP) with value $Z^* = \sum_{j \in J} c_j x_j^* + \sum_{k \in K} \theta_k w_k^* + \sum_{j \in J} z_j^*$. By constraint (17) of (Rob-BP) and by the non-negativity of $z_j$ we have:

$$z_j^* = \max_{k \in K} \{d_j^k x_j^* - w_k^*, 0\}$$

and then:

$$Z^* = \sum_{k \in K} \theta_k w_k^* + \min_{x \in X} \left\{ \sum_{j \in J} c_j x_j + \sum_{k \in K} \max_{j \in J} \{d_j^k x_j - w_k^*, 0\} \right\}$$

$$= \sum_{k \in K} \theta_k w_k^* + \min_{x \in X} \left\{ \sum_{j \in J} c_j x_j + \sum_{k \in K} \max_{j \in J} \{d_j^k - w_k^*, 0\} x_j \right\}$$

$$= \sum_{k \in K} \theta_k w_k^* + \min_{x \in X} \sum_{j \in J} \tilde{c}_j x_j,$$

where the second equality follows from the binary nature of $x$.

From Lemma 2 we know that $D$ contains at least one vector $w$, which corresponds to an optimal solution, so we obtain an optimal solution. Furthermore, the run time is polynomial if the size of set $D$ is polynomial, i.e. if the number of bands is constant. This concludes the proof. \qed

---

**Algorithm 1.1** Computing an optimal robust solution of (Rob-BP)

Input: set of feasible solutions $X \subseteq \{0, 1\}^n$;

cost values $c_j \geq 0$ for all $j \in J$;

deviation values $0 = d_j^1 \leq d_j^2 < d_j^3 < \ldots < d_j^{K_j}$ for all $j \in J$;

lower and upper bounds $l_k, u_k$ for all $k \in K$.

Output: an optimal robust solution $x^* \in X$.

Step 1: a) set $D_0 := \{0\} \cup \{d_j^1 : j \in J\}$ and $D = D_0 \times \ldots \times D_{K}$;

b) compute $p = \min \{k \in K : \sum_{i=1}^k l_i + \sum_{i=k+1}^K u_i \leq n\}$;

c) set $\theta_k = l_k$ for $k = 1, \ldots, p-1$,

$\theta_k = u_k$ for $k = p+1, \ldots, K$ and $\theta_p = n - \sum_{k \in K \setminus \{p\}} \theta_k$.

Step 2: for each $w \in D$:

a) define the values $\bar{d}_j = \{\max_{k \in K} \{d_j^k - w_k\}, 0\}$, for all $j \in J$;

b) solve the deterministic optimization problem $\min_{x \in X} \tilde{c}(x)$ with $\tilde{c}_j = c_j + \bar{d}_j$;

c) define $\min_{x \in X} \tilde{c}(x)$ and $x^*(w) = \arg \min_{x \in X} \tilde{c}(x)$.

Step 3: choose $w^*$ from $D$ with minimum cost $\min_{x \in X} \tilde{c}(x) + \theta w$.
Remark. We note that Algorithm 1 can be transferred to a robust \( \alpha \)-approximation algorithm if instead of solving \( \min_{x \in X} \hat{c}(x) \) to optimality we compute an \( \alpha \)-approximation of the deterministic problem.

5 Defining a probability bound of constraint violation

In this section, we analyze the probability that a robust optimal solution \( x^* \) becomes infeasible: \( x^* \) is indeed completely protected against deviations captured by the multi-band scenario set, but it may still become infeasible under deviations that lie outside the set. In contrast to the bounds defined in [5] and [8], which use a priori information about the not completely known distribution of the deviations (specifically, they assume symmetric distributions with symmetric range), we define a bound that exploits historical data available on the uncertain coefficients. Our basic assumption is that for each coefficient \( a_{ij} \), the corresponding sample mean.

Hoeffding’s Inequality [22]: Hoeffding’s Inequality bounds the probability that the difference between the sample mean and the actual mean of a distribution exceeds a fixed threshold.

Consider the robust optimization problem (Rob-MILP) under a multi-band uncertainty set defined as in Section 7 and let \( x^* \) be a robust optimal solution to (Rob-MILP). Suppose that the uncertain coefficients \( a_{ij} \) are independent random variables and that for each \( a_{ij} \), we have \( W > 0 \) samples \( a_{ij}^{(1)}, a_{ij}^{(2)}, \ldots, a_{ij}^{(W)} \), with each sample lying in the overall deviation range, i.e. \( a_{ij}^{(s)} \in [\bar{a}_{ij} - d_{ij}^{K-}, \bar{a}_{ij} + d_{ij}^{K+}] \), \( s = 1, \ldots, W \). This is a very reasonable assumption in real-world problems, where data about the past behavior of the uncertainty are commonly available. Through this samples, we can define the sample mean \( \mu_{ij} = 1/W \sum_{s=1}^{W} a_{ij}^{(s)} \) of \( a_{ij} \) and define a new typology of probabilistic bound, as formalized in the proposition that follows. We note that our bound holds with a bounded probability, since it is defined using the well-known Hoeffding’s Inequality [22]: Hoeffding’s Inequality bounds the probability that the difference between the sample mean and the actual mean of a distribution exceeds a fixed threshold.

Proposition 2. Consider the robust optimization problem (Rob-MILP) under a multi-band uncertainty set defined as in Section 7 and let \( x^* \) be a robust optimal solution to (Rob-MILP). Suppose that the uncertain coefficients \( a_{ij} \) are independent random variables and that for each \( a_{ij} \), we have \( W > 0 \) samples \( a_{ij}^{(s)} \in [\bar{a}_{ij} - d_{ij}^{K-}, \bar{a}_{ij} + d_{ij}^{K+}] \), \( s = 1, \ldots, W \) is available and denote by \( \mu_{ij} \) the corresponding sample mean.

Given a constraint \( i \in I \) and a constant \( t \geq 0 \), the probability \( P_i^V(x^*) \) that the robust optimal solution \( x^* \) violates \( i \) (i.e., \( P_i^V(x^*) = P[a_i^*(x^*) > b_i] \)) is such that:

\[
P_i^V(x^*) \leq \exp \left( -t b_i + \sum_{j \in J} \ln B_{ij}[t, x^*] \right),
\]

where

\[
B_{ij}[t, x^*] = \frac{1}{a_{ij}^{K+} + a_{ij}^{K-}} \left\{ \left( \bar{a}_{ij} + a_{ij}^{K+} - \left( \mu_{ij} + x_j^* \left( d_{ij}^{K+} + a_{ij}^{K-} \right) \sqrt{\frac{1}{2W \ln \beta_{ij}}} \right) \right) \exp \left( t x_j^* (\bar{a}_{ij} - a_{ij}^{K-}) \right) - \right. \\
- \left. \left( \bar{a}_{ij} - a_{ij}^{K-} - \left( \mu_{ij} + x_j^* \left( d_{ij}^{K+} + a_{ij}^{K-} \right) \sqrt{\frac{1}{2W \ln \beta_{ij}}} \right) \right) \exp \left( t x_j^* (\bar{a}_{ij} + a_{ij}^{K+}) \right) \right\}.
\]
Moreover, for fixed $\tau > 0$, the bound (25) holds with probability greater than or equal to
\[
\prod_{j \in J} (1 - \beta_{ij}) = \prod_{j \in J} \left[ 1 - \exp \left( -\frac{2\tau^2 W}{x_j^4 (d_{ij}^{K^+} + d_{ij}^{K^-})^2} \right) \right].
\]

Proof. In order to prove the result, we will use the well-known Markov’s Inequality and Hoeffding’s Inequality [22]. Given $x^*$ and $t > 0$, the probability of violation of constraint $i$ is:
\[
P(V(x^*)) = P \left( \sum_{j \in J} a_{ij} x^*_j > b_i \right) \leq \exp \left( -t b_i \prod_{j \in J} E \left[ \exp \left( t a_{ij} x^*_j \right) \right] \right),
\] (26)
where inequality (1b) derives from Markov’s Inequality and the independence of $a_{ij}$. We are then interested in bounding the moment generating function $E \left[ \exp \left( \gamma x^*_j \right) \right]$ in the r.h.s. of (1b), using the available samples $a_{ij}^\sigma, \sigma = 1, \ldots, W$. To this end, we can consider the following formula, that exploits the convexity of the exponential function and holds for given $\gamma > 0$ for a bounded random variable $V$:
\[
E \left[ \exp \left( \gamma V \right) \right] \leq \frac{1}{u - l} \left[ (u - E[V]) \ e^{\gamma l} + (E[V] - l) \ e^{\gamma u} \right].
\] (27)
To use this formula, since we do not know the real mean $E[a_{ij}]$, in the following passages we derive a bound on $E[a_{ij}]$.

As first step, for each coefficient $a_{ij}$, we use Hoeffding’s Inequality to bound the probability that the difference between the sample mean and the actual mean is above a value $\tau > 0$, namely:
\[
P \left[ x^*_j E[a_{ij}] - x^*_j \mu_{ij} \geq \tau \right] = P \left[ E[a_{ij}] - \mu_{ij} \geq \frac{\tau}{x^*_j} \right] \leq \exp \left( -\frac{2 \tau^2 W}{x^4_j (\bar{a}_{ij} + d_{ij}^{K^+} - \bar{a}_{ij} - d_{ij}^{K^-})^2} \right) = \exp \left( -\frac{2 \tau^2 W}{x^4_j (d_{ij}^{K^+} + d_{ij}^{K^-})^2} \right).
\]

By letting $\beta_{ij} = \exp \left( -\frac{2 \tau^2 W}{x^4_j (d_{ij}^{K^+} + d_{ij}^{K^-})^2} \right)$ and by reorganizing the equality through simple algebra operations we get $\tau = x^4_j (d_{ij}^{K^+} + d_{ij}^{K^-}) \sqrt{\frac{1}{2W \ln \beta_{ij}}}$ and finally:
\[
P \left[ E[a_{ij}] - \mu_{ij} \geq x^*_j (d_{ij}^{K^+} + d_{ij}^{K^-}) \sqrt{\frac{1}{2W \ln \beta_{ij}}} \right] \leq \beta_{ij}.\] (28)
From inequality (28), we can derive the following bound for the (unknown) actual mean of $a_{ij}$:

$$E[a_{ij}] \leq \mu_{ij} + x_j^* \left( d_{ij}^{K+} + d_{ij}^{K-} \right) \sqrt{\frac{1}{2W \ln \beta_{ij}}}.$$  \hspace{1cm} (29)

that holds with probability at least $1 - \beta_{ij}$.

We can then use the bound (29) on the actual mean in the bound (27) on the moment generating function, to finally reach our objective, namely defining a bound on $E[\exp(t a_{ij} x_j^*)]$. In our case, the adaptation of (27) is:

$$E[\exp(t a_{ij} x_j^*)] \leq \frac{1}{(d_{ij}^{K+} + d_{ij}^{K-})} \cdot \left\{ (\bar{a}_{ij} + d_{ij}^{K+} - E[a_{ij}]) \exp(t x_j^* (\bar{a}_{ij} - d_{ij}^{K-})) - (\bar{a}_{ij} - d_{ij}^{K-} - E[a_{ij}]) \exp(t x_j^* (\bar{a}_{ij} + d_{ij}^{K+})) \right\}. \hspace{1cm} (30)$$

where we note that we have not yet substituted $E[a_{ij}]$.

Finally, we substitute the bound (30) in (26), thus obtaining the bound $B_{ij}[t, x^*]$ of the statement of the Proposition, that holds with probability greater than or equal to $\prod_{j \in J} (1 - \beta_{ij})$. We then have:

$$\exp(-t b_i) \prod_{j \in J} E[\exp(t a_{ij} x_j^*)] \leq \exp(-t b_i) \prod_{j \in J} B_{ij}[t, x^*] = \exp \left( -t b_i + \sum_{j \in J} \ln B_{ij}[t, x^*] \right),$$

ending the proof.

6 Conclusions and Future Work

In this work, we presented new theoretical results about multi-band uncertainty in Robust Optimization. Surprisingly, this natural refinement of the classical single band model by Bertsimas and Sim has attracted very little attention and we have thus worked on filling the existing knowledge gap. Our ongoing research is currently focused on refining the cutting plane method and intensifying the computational experiments to other relevant real-world problems, considering realistic instances defined in collaboration with our industrial partners.
